Acknowledgments

My thanks go to R. Paulen, J. Pawlowicz, M. Fenton, J. Sarnecki, J. Weiss, B. Brown and D. Pana for their assistance in the field. The report was reviewed by R. Paulen, R.F. Davie, and G. Hippolt-Squair. Preparation of the report for publication was undertaken by J. Weiss and M. Protz. Technical editing was performed by R.F. Davie and G. Hippolt-Squair.

Abstract

The Sawn Lake map area (NTS 84B/13) lies within the southern Buffalo Head Hills in north-central Alberta. This area covers the northwestern part of the Buffalo Head Hills kimberlite field, within which 38 kimberlites have been discovered since 1997. Till occurs near the surface throughout much of the area.

This report presents geochemical results for the <63 µm fraction of 67 till samples and 1 glaciofluvial sand sample from the Sawn Lake map area. Fifty-four of the till samples and the glaciofluvial sample were collected in 2002. Twelve till samples discussed in this report were collected before 2002 and analyzed (reanalyzed) along with the 2002 samples. Kimberlite-indicator mineral (KIM) data from these samples were released previously.

Tills of the Sawn Lake area typically contain about 40% clay, 30% silt and 30% sand. Intriguing compositional differences exist between ablation till (ice-stagnation deposits) and non-ablation till (which includes basal till). On average, the ablation till has higher MgO, CaO, calcite and dolomite values, whereas the non-ablation till has higher Mo, U, Sb and Se values. These differences may reflect a higher component of Cretaceous shale, particularly organic-rich shale, in the basal till component of the non-ablation till compared to a somewhat greater amount of limestone and dolomite debris, derived from distant Paleozoic strata, in the ablation till.

1 Introduction

1.1 Overview

The Sawn Lake map area (NTS 84B/13) covers the northwestern part of the Buffalo Head Hills kimberlite field, within which 38 kimberlites have been discovered since 1997. Approximately two-thirds of these kimberlites contain diamonds, with estimated grades of up to 55 carats per hundred tonnes (Hood and McCandless, 2004). Nineteen (50%) of the known kimberlites within the Buffalo Head Hills kimberlite field occur within the Sawn Lake map area (Hood and McCandless, 2004).

The primary impetus for the Alberta Geological Survey (AGS) to undertake till sampling in the Sawn Lake area was to collect information on kimberlite-indicator mineral (KIM) dispersal within a known kimberlite field to

- help diamond explorers optimize exploration programs elsewhere in northern Alberta;
- assess the effectiveness of regional till KIM surveys compared to regional stream-sediment KIM surveys; and
- provide information that may lead to the discovery of additional diamondiferous kimberlites in the Sawn Lake area.

In addition to the KIM samples, which were processed to concentrate heavy minerals, a second set of samples was collected in 2002 for geochemical analyses of the <63 µm fraction. These geochemical results form the basis of this report.

This report provides geochemical data for the <63 µm fraction of 68 sediment samples collected within the Sawn Lake map area: 55 till samples collected in 2002, 1 glaciofluvial sand sample collected in 2002, and 12 till samples collected by the AGS prior to 2002. Prior et al. (2005) discussed heavy-mineral concentration and KIM grain-picking results for the 2002 samples. Prior (2007) documented the results of microprobe analyses of heavy mineral grains from the 2002 survey. Keith (2004) reported on microprobe analyses of Cr-rich amphiboles and clinopyroxenes obtained from a subset of the 2002 till samples. In addition, Prior et al. (2003a, b) presented preliminary KIM results.

1.2 Location and Physiography

The Buffalo Head Hills of north-central Alberta form a northerly trending upland region lying between the Peace River Lowland (Cadotte Plain) to the west and the Wabasca Lowland (Loon Lake Plain) to the east (Pettapiece, 1986; Figure 1). The Sawn Lake map area (NTS 84B/13) lies within the southern Buffalo Head Hills, approximately 50 km northwest of the community of Red Earth Creek. In general, the western two-thirds of the survey area are characterized by a relatively flat upland with hummocky terrain dissected by meltwater channels and intermittent bogs. The eastern third of the area lies on the gently east-sloping flanks of the Buffalo Head Hills. Maximum elevation is 820 m above mean sea level, almost 300 m above the Wabasca Lowland to the east. Oil and gas production occurs in the region, and some areas of forest have been logged.

2 Till and Glaciofluvial Sand Sampling in the Sawn Lake Area Before 2002

Surface till and glaciofluvial sediment samples collected by AGS within the Sawn Lake map area prior to 2002, for KIM processing and geochemical analyses, are listed in Table 1. All of these samples were collected adjacent to roads. The samples reported by Eccles et al. (2001) were collected as part of a regional KIM sampling program covering the Peerless Lake 1:250 000 map area (NTS 84B). The

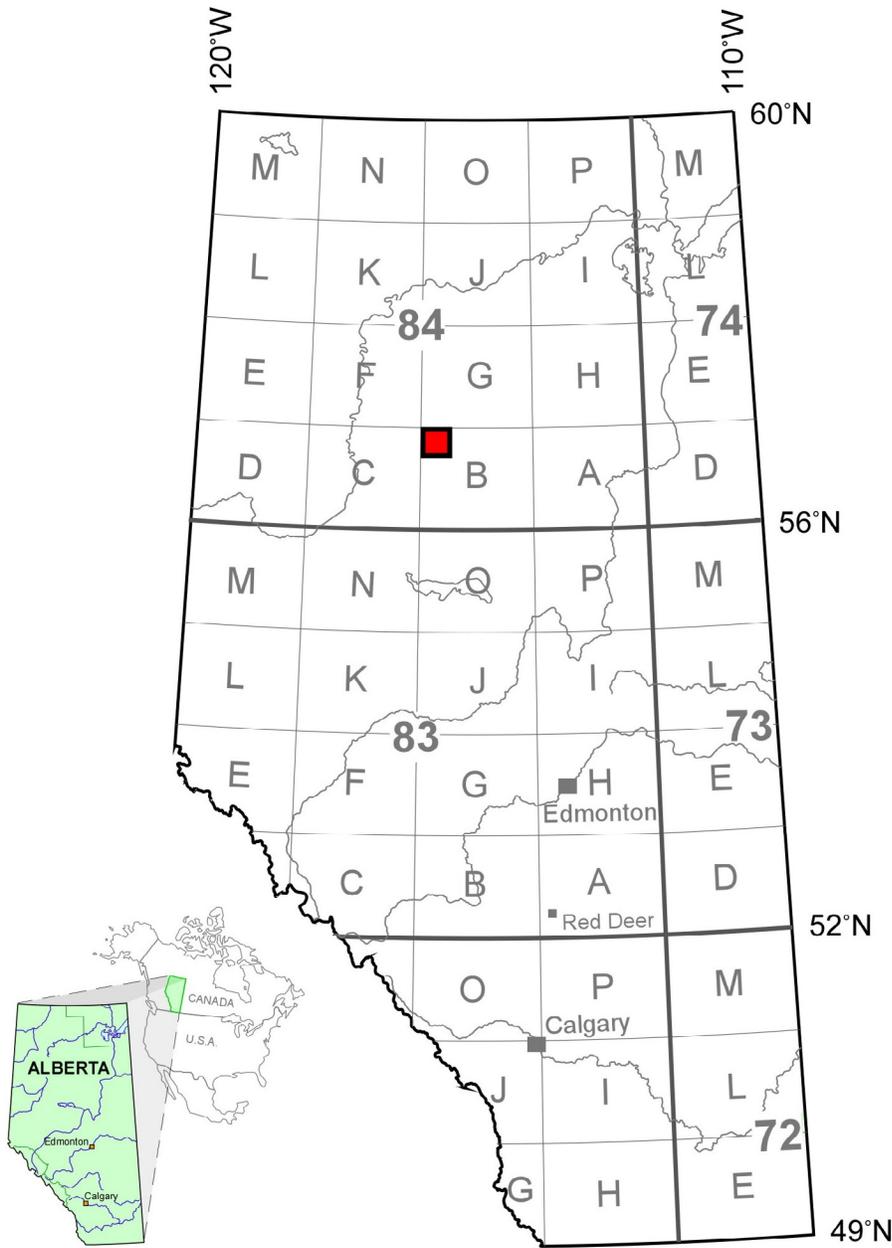

Figure 1. Location of the Sawn Lake map area (NTS 84B/13).

remaining samples listed in Table 1 were collected as part of the AGS surficial mapping program. Interestingly, sample NAT95-134, which returned 152 possible pyrope grains, was collected in 1995 before the discovery of kimberlites in the Buffalo Head Hills (Fenton and Pawlowicz, 1997).

Geochemical analyses of the 2002 Sawn Lake area samples were undertaken by Acme Laboratories of Vancouver (see Section 5 for a description of methods). In addition, archived pulps of 12 previously collected till samples (NAT96-216, NAT98-260, RE98-84B-36-001, RE98-84B-37-001, RE98-84B-39-001, RE98-84B-40-001, RE98-84B-41-001, RE98-84B-45-001, RE98-84B-53-001, RE98-84B-165-001, 1401G and 1402G) were retrieved from storage and submitted to Acme in the same sample batch as the 2002 samples. The Acme data for the pre-2002 samples are used to augment the results obtained from the 2002 samples.

3 Geology

3.1 Bedrock Geology

3.1.1 Sedimentary Rocks

The Buffalo Head Hills are underlain by Cretaceous strata of the Western Canada Sedimentary Basin (Figure 2). Maps by Green et al. (1970) and Hamilton et al. (1999) show the area near Sawn Lake to be underlain by the dark grey shale and silty shale of the Upper Cretaceous Smoky Group. However, recent palynological results indicate that the uppermost part of the Buffalo Head Hills in the Sawn Lake area is underlain by Upper Campanian rocks, including sandstone, correlative with the Wapiti Formation (Pawlowicz et al., 2005a, b). Stratigraphic markers in the lower part of the Upper Cretaceous succession indicate nearly horizontal dips in the Sawn Lake area (Chen and Olson, 2005).

3.1.2 Kimberlites

The Buffalo Head Hills kimberlite field, which occurs in the southern Buffalo Head Hills and the adjacent Loon Lake Plain (Loon River lowland) to the east (Figure 2), contains a minimum of 38 occurrences of kimberlite (Hood and McCandless, 2004). These kimberlites are hosted by a Cretaceous succession composed dominantly of marine shales of the Shaftesbury Formation and Smoky Group, which are separated by deltaic to marine sandstones of the Dunvegan Formation (Green et al., 1970; Hamilton et al., 1999). Some kimberlite pipes of the Buffalo Head Hills field are quite large, up to 40 hectares, based on drillhole information and geophysical modelling (Skelton et al., 2003). Three kimberlites are exposed at surface and several of the kimberlites form bedrock highs, which may be accompanied by topographic highs due to their greater resistance to weathering and glacial erosion relative to the poorly indurated Cretaceous sedimentary rocks. In general, kimberlites of the Buffalo Head Hills field consist primarily of crater facies, juvenile lapilli-rich, olivine (crystal) tuffs (Boyer et al., 2003; Eccles, 2004). Perovskite (U-Pb) dates obtained on three Buffalo Head Hills kimberlites indicate emplacement ages of 86 ± 3 , 87 ± 3 and 88 ± 5 Ma for kimberlites K7A, K5 and K14, respectively (Carlson et al., 1999).

Of the 38 kimberlites within the Buffalo Head Hills field, 26 are known to contain diamonds. Kimberlites in the northern part of this field tend to have higher diamond contents. The northern group of kimberlites includes K252, which has the highest known diamond content in the field, with an estimated grade of 55 carats per hundred tonnes (Hood and McCandless, 2004).

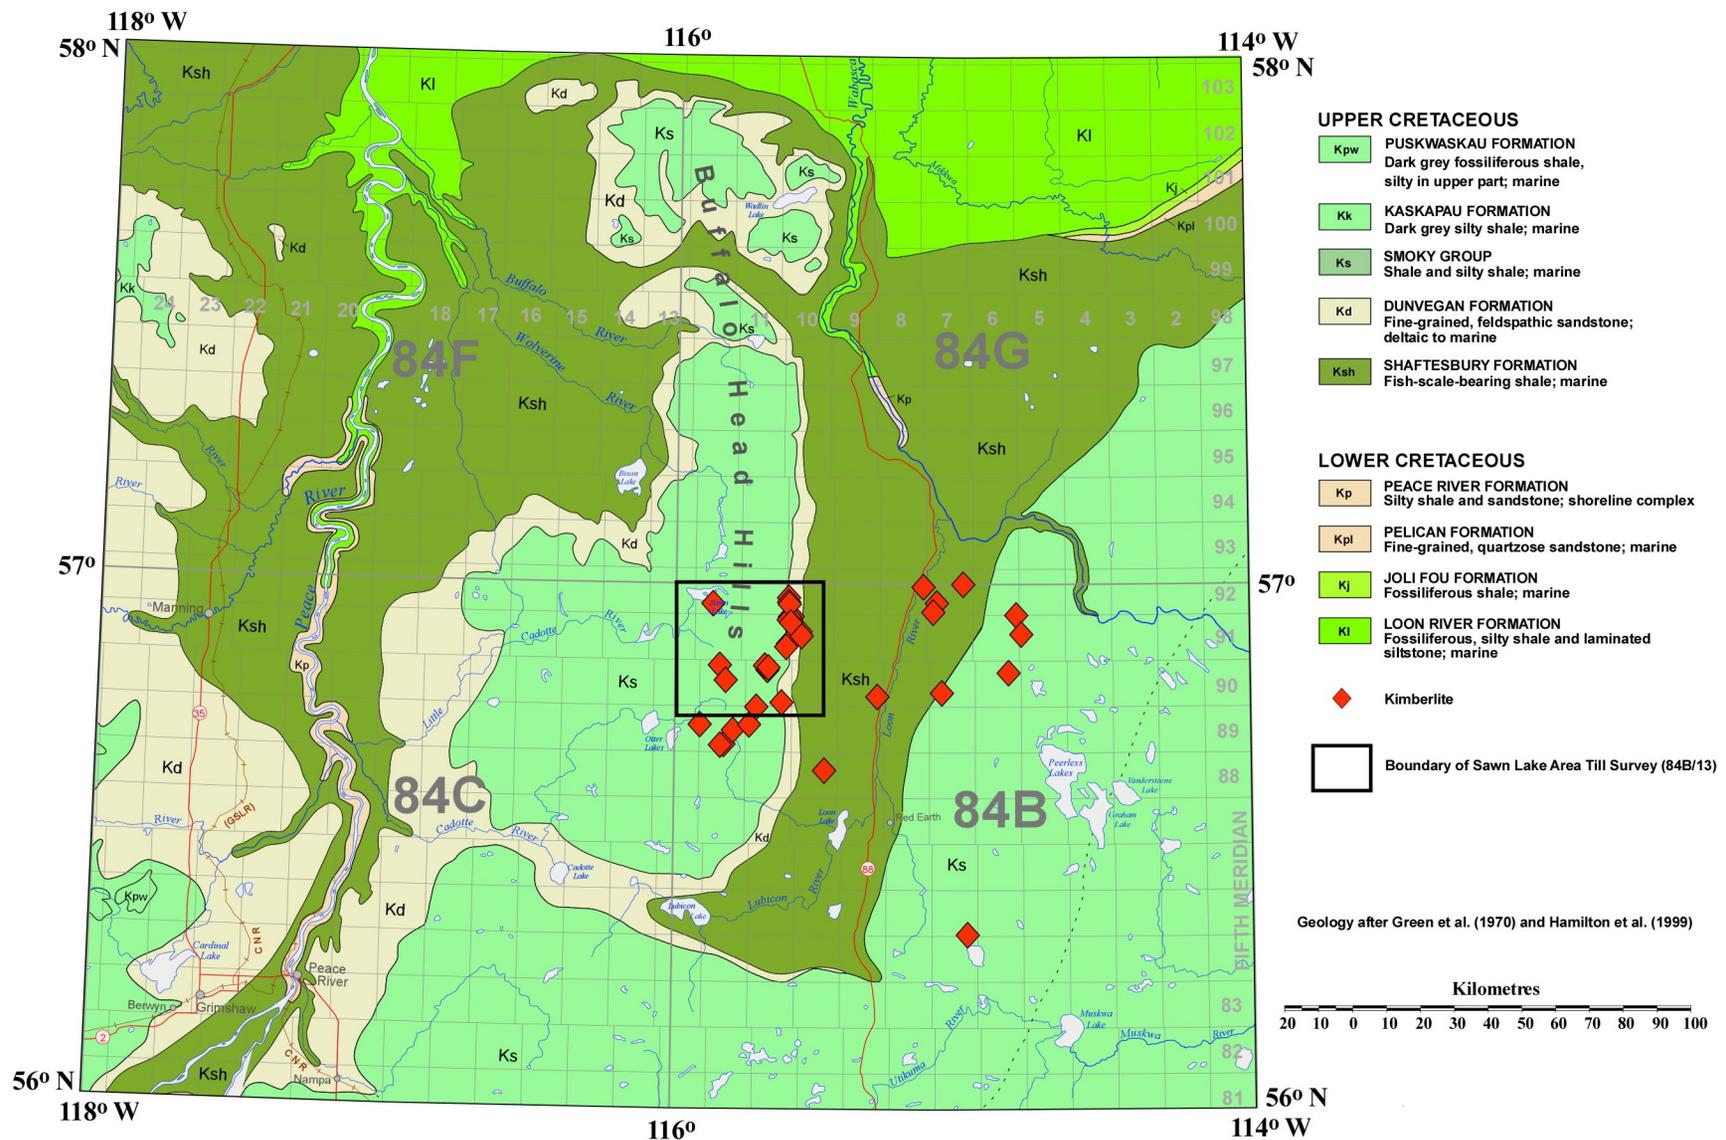

Figure 2. Bedrock geology of the Buffalo Head Hills area (NTS 84B, C, F and G).

3.2 Surficial Geology

3.2.1 Surficial Materials

The surficial geology of the southeastern Buffalo Head Hills (NTS 84B/NW), which includes the Sawn Lake (NTS 84B/13) area, has been mapped at 1:100 000 scale (Paulen et al., 2003). Subsequent detailed 1:50 000 mapping of the Sawn Lake area (Trommelen, 2004; Trommelen et al., 2006) provides excellent detail on the distribution of surficial sediments within the study area. The present surficial geology in the region is largely the result of the advance and retreat of the Late Wisconsin Laurentide Ice Sheet (Lostwood Glaciation; Fenton, 1984). Drift thickness throughout the area ranges from thin (<1 m) veneers, with rare bedrock exposures, to greater than 60 m (Pawlowicz and Fenton, 2005).

Much of the Sawn Lake area is covered by moraine (till), of which there are two dominant types:

- **Basal till:** Basal till occurs at the surface along the flanks of the Buffalo Head Hills and in the Wabasca Lowland. The till is characterized by nonsorted diamicton with a silty clay matrix that is commonly fissile and compact, and contains 1%–5% clasts ranging in size from granules to boulders. Indurated clasts are typically faceted and glacially polished. Topographically, the deposits form flat, low-relief plains. This material is interpreted as till deposited directly by glacial ice without transport or modification by water (cf. Dreimanis, 1990). Due to the silty clay texture of the till and generally low topographic gradient, the water table is often perched and the moraine plains host numerous Holocene fens and peat bogs (Trommelen, 2004; Paulen et al., 2006).
- **Ablation till:** A considerable region of hummocky terrain, with circular or ‘doughnut’ morphology, occurs on the uplands of the Buffalo Head Hills (stagnant-ice moraine). The material consists of nonsorted diamicton with a matrix ranging from sandy silt to silty clay. The matrix is typically poorly compacted and local sand lenses (medium to coarse grained) are common. The diamicton contains 5%–10% clasts, with indurated clasts that are more angular and less polished than the faceted clasts of basal till. The ablation till may be weakly stratified, likely due to the presence of more water during deposition. Topographically, the stagnant-ice moraine is typified by undulating to hummocky terrain consisting of roughly equidimensional hills and depressions. Relief is often greater than 2 m, which creates a landscape significantly different from areas covered by basal till. Stagnant-ice moraine, thought to represent glacial sedimentation during glacial retreat and ice stagnation, may include glaciofluvial and glaciolacustrine material in addition to till. The stagnant-ice moraine often forms doughnuts, consisting of a roughly circular hill composed of till with a central depression infilled with lacustrine sediments and subsequent bog peat (Trommelen, 2004; Paulen et al., 2006).

Glacial meltwater valley systems, extending for up to 20 km in length, are found throughout the survey area. These valleys, up to 300 m wide and 50 m deep, have significant negative topographic relief on the landscape that exceeds the local relief of hummocky topography. Ice-contact sediment occurs in the form of small kames (up to 0.5 km across), eskers (averaging 1 km in length) and small crevasse-fill deposits. These ice-contact deposits consist of poorly sorted, massive to crudely stratified gravel, sand and minor silt. Glaciolacustrine sediments are rare in the Sawn Lake region but occur in the nearby Loon Lake Plain (Paulen et al., 2003). Colluvium, in the form of slumped deposits, generally occurs as a veneer along several of the main valleys in the study area. Modern fluvial sediment is dominantly fine grained with organic detritus and minor gravel and sand in more developed streams. Organic deposits occur throughout the map area in regions of poor surface drainage, such as moraine plains, and in depressions within stagnant-ice moraine (Trommelen 2004; Paulen et al., 2006). Pre-Laurentide, quartzite-bearing gravels have been identified beneath a veneer of glacial sediments in the southwestern part of the Sawn Lake map area (Trommelen, 2004; Trommelen et al., 2006).

3.2.2 Late Wisconsin Glacial History

Figure 3 is a reconstruction of Late Wisconsin ice flow in northern Alberta. Glacial advances in northern Alberta originated from the Laurentide Ice Sheet, which generally flowed southwest across central Alberta (Fulton, 1989; Fenton et al., 2003). According to regional studies, ice advanced to its Late Wisconsin limit approximately 23–24 ka and retreated from the Buffalo Head Hills by 11 ka (^{14}C ; Dyke et al., 2002, 2003; Dyke, 2004). Local evidence for the southwesterly flow of the Late Wisconsin Laurentide Ice Sheet across the Sawn Lake area during the glacial maximum includes

- a sculpted crag-and-tail feature at the K5 kimberlite outcrop (Skelton et al., 2003; Paulen et al., 2003);
- poorly developed flutings, trending west-southwest, formed in the upper part of the Buffalo Head Hills in a local area where the drift forms only a thin (<2 m) veneer over the Cretaceous mudstone (Paulen et al., 2003); and
- striae on a polished surface of the K6 kimberlite outcrop, indicating south-southwest glacial flow (R. Paulen, pers. comm., 2005).

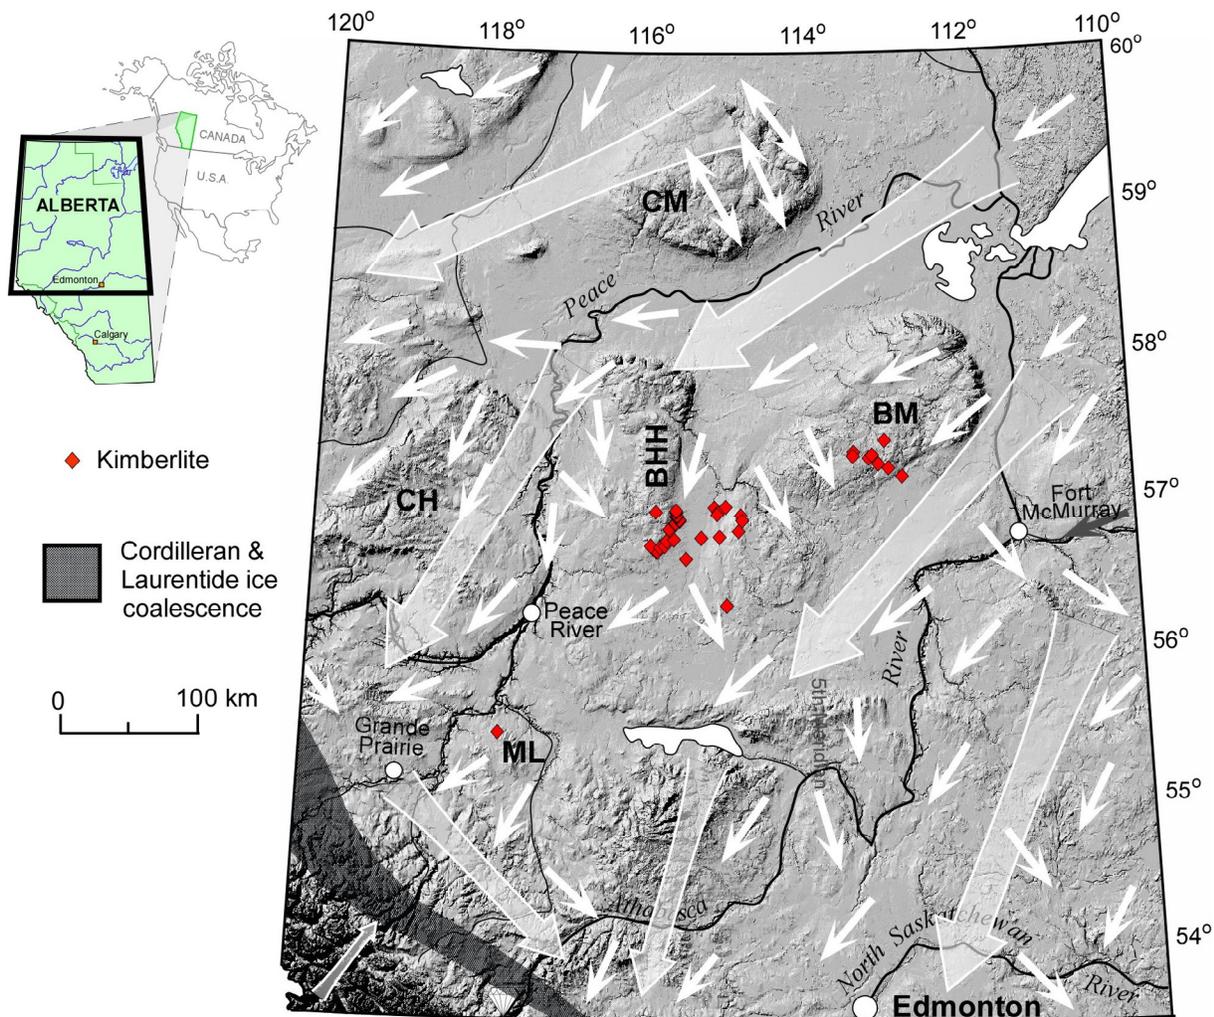

Figure 3. Flow of the Laurentide Ice Sheet during the Late Wisconsin (from Fenton et al., 2003). Large arrows indicate ice flow at glacial maximum (derived from Prest et al., 1968; Fulton, 1989); and smaller arrows indicate general flow directions of latest Late Wisconsin ice (Mathews, 1980; Klassen 1989; R. Paulen, pers. comm., 2005). Abbreviations: CH, Clear Hills; CM, Caribou Mountains; BHH, Buffalo Head Hills; BM, Birch Mountains; ML, Mountain Lake.

Recession of the western margin of the Laurentide Ice Sheet began around 14 ka (^{14}C ; Dyke, 2004). Saint-Onge (1972) indicated that drainage of the Lesser Slave Lake valley occurred about 11 000 years ago, based on a bulk gyttja date of $11\,400 \pm 190$ years before present (^{14}C ; GSC-1049; Lowdon et al., 1971). Recently, precision ^{14}C accelerator mass spectrometry (AMS) dates on seeds and wood obtained from the base of lake cores in the Utikuma Lake area support this minimum deglacial age (Squires et al., 2006). During glacial retreat, the ice margin retreated down drainage, essentially ponding all meltwater in proglacial lakes and trapping the terrestrial and meltwater drainage from the recently deglaciaded eastern Cordillera and Foothills (cf. Mathews, 1980). This created an unstable ice margin. Surging ice lobes advanced and retreated within the proglacial lakes, modifying or obliterating older streamlined landforms and creating strongly fluted terrain in the lowlands. Ice was often confined by topography and deglacial streamlined landforms commonly deviate considerably from glacial maximum flow directions. Sometime after glacial maximum, southward-flowing ice (Peace River lobe) in the northern Peace River valley advanced out of the Peace River valley from the northwest and flowed over the southwestern flank of the Buffalo Head Hills (Mathews, 1980; R. Paulen, pers. comm., 2005). This southeasterly surge was deflected by a large mass of surging ice that was flowing south-southwest along the Loon River valley. It is likely that thinner ice stagnated on top of the Buffalo Head Hills, while thicker ice in the valleys continued to actively flow (R. Paulen, pers. comm., 2005).

4 Field Program

4.1 Sample Distribution

The planned till-sample distribution was based on a minimum density of one sample per 16 km^2 , with higher density of up to one sample per 2 km^2 in the area near the K4 kimberlite complex. Existing AGS till samples with KIM analyses (Table 1), collected along roads in map area 84B/13 prior to 2002, were incorporated into the sampling plan to avoid duplication.

During the 2002 sampling program, till samples were collected from 55 sites, an average density of approximately one sample per 16 km^2 (Figure 4). Inclusion of 12 pre-2002 till samples increases the data density, mainly in the central part of the area near the K4 kimberlite complex (K4A, K4B and K4C kimberlites). In addition to the till samples, one sand-rich sample (2022M) of glaciofluvial (ice-advance proglacial outwash) material was collected beneath 2 m of till.

4.2 Sample Collection

Travel to sites in 2002 was by trucks, four-wheel-drive all-terrain vehicles, foot traverses and a helicopter flight (one site). Access to field sites away from roads was commonly along seismic lines. At each sampling site (except for those with roadcuts) a pit was dug, generally to a depth at which the till matrix contains calcite as determined by reaction with dilute (10%) HCl. The limit of intense in situ leaching of matrix calcite commonly occurs at a depth 10–30 cm below the first appearance of limestone clasts (Figure 5; cf. Dreimanis, 1957; Merritt and Muller, 1959). The till KIM sample was then collected from the bottom of the pit over a 20 to 30 cm interval. Sampling depth intervals typically varied from as shallow as 55–75 cm to as deep as 130–150 cm. The KIM till sample was added to a labelled 23 litre (5 gallon) plastic pail until the pail was nearly full. The weight of the KIM samples delivered to the lab for processing generally varied between 25 and 35 kg. In addition to the KIM sample, a 1–2 kg till sample was collected near the bottom of the pit and placed in a labelled plastic bag for geochemical analyses of the $<63\text{ }\mu\text{m}$ fraction. Each pair of KIM and associated geochemical samples was assigned the same four numbers, with a suffix of M for the KIM (mineralogy) sample and a suffix of G for the geochemical sample (e.g., 2001M and 2001G). Once sampling was completed, the pit was filled in. One pair of glaciofluvial sand samples (2022M and 2022G) was collected during the 2002 program in a manner similar to that described for the till samples. Sample descriptions are provided in Prior et al. (2005).

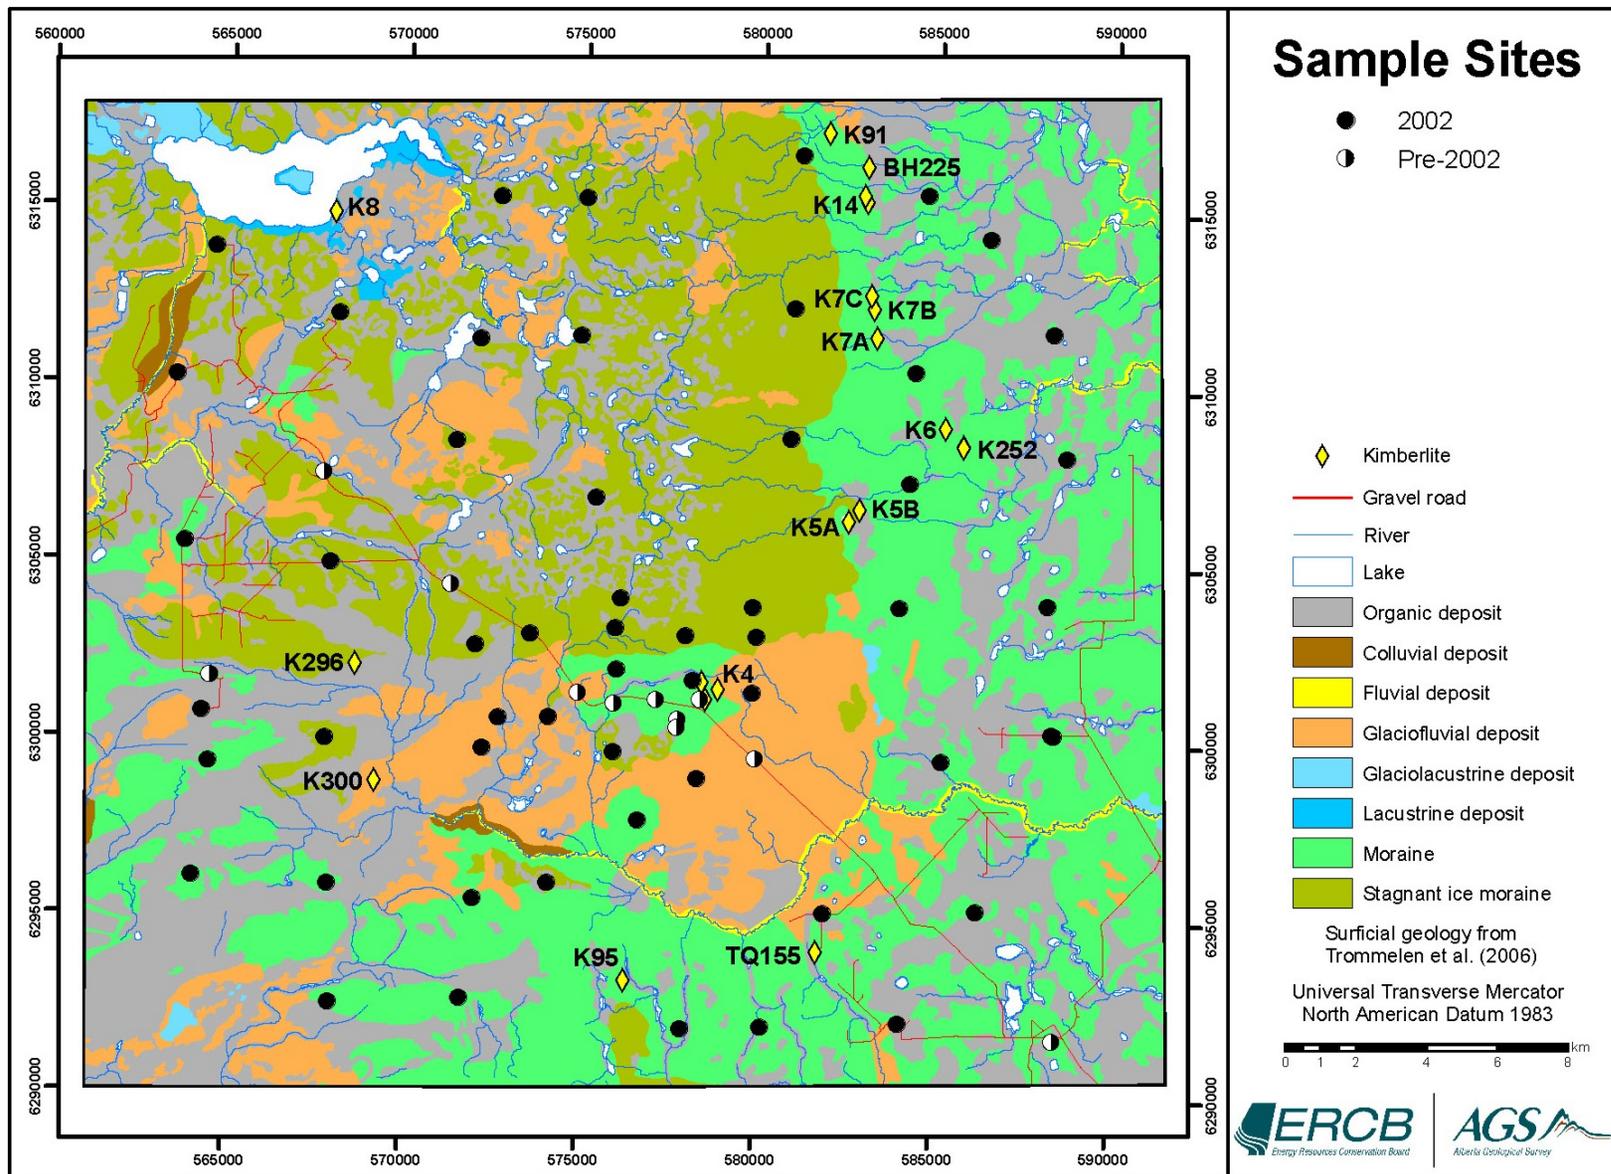

Figure 4. Sawn Lake (NTS 84B/13) till survey, southern Buffalo Head Hills, Alberta: 2002 and pre-2002 sample sites.

Figure 5. Clasts in a vertical till exposure (sample site 2525), indicated by coloured arrows (red, igneous; yellow, oxidized mudstone; blue, limestone); shovel handle marked in centimetres; 80 cm mark on handle, below which carbonate clasts are present, is at ~80 cm below ground surface.

5 Laboratory Methods

5.1 Initial Sample Preparation

5.1.1 2002 Samples

Initial sample preparation of the 55 samples collected in 2002 was performed at the AGS laboratory in Edmonton. Samples were air dried at room temperature before being manually disaggregated using a porcelain mortar and pestle. Then, the samples were sieved using nested 2 mm, 1 mm and 63 μm (250 Tyler mesh) stainless-steel sieves. The <63 μm fraction was split into material for external geochemical analysis and material to be archived. Analytical splits of the <63 μm samples, along with laboratory duplicates (<63 μm sample splits) and standard samples, were shipped to Acme Analytical Laboratories (Acme), Vancouver, British Columbia for geochemical analyses.

5.1.2 Pre-2002 Samples

Archived <63 μm sample material from the 12 pre-2002 AGS samples (NAT96-216, NAT98-260, 1401G, 1402G, and the RE98 series samples) were retrieved from storage and submitted to Acme for geochemical analyses in the same batch as the 2002 samples.

5.2 Analytical Procedures

5.2.1 Fusion ICP-ES Multi-Element Analyses, LECO Infrared Adsorption Determination of C and S, and Gravimetric Determination of Loss-on-Ignition (Acme Group 4A)

Acme carried out fusion digestion of the samples, followed by inductively coupled plasma–emission spectrometry (ICP-ES) analysis, to determine abundances of SiO₂, Al₂O₃, Fe₂O₃ (total Fe), MgO, CaO, Na₂O, K₂O, P₂O₅, MnO, Cr₂O₃, Ba, Ni and Sc (Appendix 1). A 0.2 g sample aliquot was weighed into a graphite crucible and mixed with 1.5 g of LiBO₂ flux, then the flux-sample charge was heated in a muffle furnace for 15 minutes at 1050°C. The molten mixture was removed and immediately poured into 100 mL of 5% HNO₃ (ACS-grade nitric acid in demineralized water). The solution was shaken for 2 hours, and then an aliquot was poured into a polypropylene test tube. Sample solutions were aspirated into a Jarrel Ash Atomcomp Model 975 ICP emission spectrometer (J. Gravel, pers. comm., 2004).

For C and S determinations, 0.1 g of sample pulp (and added flux) was ignited at >1650°C in an induction furnace. Released C and S were measured by infrared adsorption using a LECO C244 carbon-sulphur analyzer. The results represent the total amount of C and S in all forms (J. Gravel, pers. comm., 2004).

For loss-on-ignition (LOI) determinations, a 1 g sample split was ignited for 90 minutes at 950°C, cooled in a desiccator, and then weighted; the difference is expressed as per cent loss-on-ignition (J. Gravel, pers. comm., 2004).

5.2.2 Fusion ICP-MS Multi-Element Analyses (Acme Group 4B)

Acme completed fusion digestion of the samples, followed by inductively coupled plasma–mass spectrometry (ICP-MS) analysis using the following methodology.

A 0.2 g sample aliquot was weighed into a graphite crucible and mixed with 1.5 g of LiBO₂ flux. The flux-sample charge was heated in a muffle furnace for 15 minutes at 1050°C, then the molten mixture was removed and immediately poured into 100 mL of 5% HNO₃ (ACS-grade nitric acid in demineralized water). The solution was shaken for 2 hours, then an aliquot was poured into a polypropylene test tube. Sample solutions were aspirated into a Perkin-Elmer Elan 6000 ICP mass spectrometer (J. Gravel, pers. comm., 2004). Determinations were made for the following 29 elements: Co, Cs, Ga, Hf, Nb, Rb, Sn, Sr, Ta, Th, U, V, W, Zr, Y, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb and Lu (Appendix 1).

5.2.3 Four-Acid ICP-ES/MS Multi-Element Analyses (Acme Group 1EX)

Acme completed four-acid digestion of the samples, followed by inductively coupled plasma–emission spectrometry (ICP-ES) and inductively coupled plasma–mass spectrometry (ICP-MS) analyses using the following methodology. Splits of 0.25 g were weighed into Teflon test tubes. A 10 mL aliquot of the acid solution (2:2:1:1 H₂O-Hf-HClO₄-HNO₃) was added, heated until fuming on a hot plate and taken to dryness. A 7.5 mL aliquot of 50% HCl was added to the residue and heated in a hot-water bath (~95°C) for 30 minutes. After cooling, the solutions were transferred to polypropylene test tubes and made up to a 10 mL volume with 5% HCl (J. Gravel, pers. comm., 2004). Solutions were analyzed by ICP-ES (Jarrel Ash AtomComp 800 ICP emission spectrometer) and ICP-MS (Perkin Elmer Elan 6000 ICP mass spectrometer). Elements with high concentrations, including major elements, were reported by ICP-ES, whereas elements with low concentrations (e.g., Be, Hf and Ta) were reported by ICP-MS. Elements that can span a broad range of concentrations (e.g., Cu, Pb and Zn) were reported by ICP-MS when low and by ICP-ES when high (J. Gravel, pers. comm., 2004, 2005). The concentrations of 41 elements were determined: Ag, Al, As, Au, Ba, Be, Bi, Ca, Cd, Ce, Co, Cr, Cu, Fe, Hf, K, La, Li, Mg, Mn, Mo, Na, Nb, Ni, P, Pb, Rb, S, Sb, Sc, Sn, Sr, Ta, Th, Ti, U, V, W, Y, Zn and Zr (Appendix 1).

5.2.4 Aqua Regia ICP-ES/MS Multi-Element Analyses (Acme Group 1F)

Acme completed aqua-regia digestion of the samples, followed by inductively coupled plasma–emission spectrometry (ICP-ES) and inductively coupled plasma–mass spectrometry (ICP-MS) analyses using the following methodology. The Acme version of aqua regia (equal proportions of HCl, HNO₃ and demineralized H₂O) was added to each sample split (7.5 g or 1.0 g) in a ratio of 6 mL of aqua regia to 1 g of sample. Samples were digested for one hour in a hot-water bath (90°–95°C), then diluted to a 20:1 mL/g final ratio (J. Gravel, pers. comm., 2001). Concentrations were determined for 63 elements: Ag, Al, As, Au, B, Ba, Be, Bi, Ca, Cd, Ce, Co, Cr, Cs, Cu, Dy, Er, Eu, Fe, Ga, Gd, Ge, Hf, Hg, Ho, In, K, La, Li, Lu, Mg, Mn, Mo, Na, Nb, Nd, Ni, P, Pb, Pr, Rb, Re, S, Sb, Sc, Se, Sm, Sn, Sr, Ta, Tb, Te, Th, Ti, Tl, Tm, U, V, W, Y, Yb, Zn and Zr (Appendix 1).

All sample solutions were analyzed by both ICP-ES and ICP-MS. ICP-ES values were reported for several elements if concentrations exceeded laboratory-determined crossover values; otherwise, ICP-MS results were reported. If the range of values for any of these elements in a batch of samples brackets the threshold value, then reported results include both ICP-ES determinations (values > threshold) and ICP-MS determinations (values < threshold). For certain elements, including Au, Sc, Tl, S, Hg, Se, Te, Ga, the incompatible trace elements (such as Y, Zr, Nb, U) and the rare-earth elements (except La), only the results from the ICP-MS were reported (J. Gravel, pers. comm., 2001).

5.2.5 Texture Analyses

Texture analyses were performed at the AGS laboratory in Edmonton. Samples were dried overnight in an oven at 40°C. The distribution of particle sizes >63 µm was determined by sieving. The size distribution of the <63 µm fraction was obtained by measuring the variation in density with time of a suspension of the sample in a dilute sodium hexametaphosphate solution (the sodium hexametaphosphate acts as a dispersing agent). Fifty grams of the <2 mm sample fraction were mixed with 125 mL of 4% sodium hexametaphosphate solution in a 1000 mL cylinder. After 1 minute of agitation, distilled water was added until the total volume was 1000 mL. Hydrometer readings were taken at 2 hours, 4 hours, 8 hours and 24 hours after agitation. A computer program was used to calculate the proportions of silt and clay in the sample, based on the density measurements (Appendix 1).

5.2.6 Carbonate Mineralogy Analyses

Carbonate mineralogy (Chittick) analyses were performed at the AGS laboratory in Edmonton. For each sample, a 1 g split of the <63 µm material was added to a flask, then 15 ml of 6N HCl were added and the volume of produced CO₂ was recorded at predetermined intervals over a period of time (normally 35 minutes). With the aid of a computer program, the percentage of calcite and dolomite in the sample was calculated based on the volume measurements (Appendix 1).

6 Analytical Data Quality

6.1 Lower Detection Limits

Elements that returned values below the lower analytical detection limit in routine samples by the various analytical methods are listed in Tables 2–5. All of the Au values by four-acid ICP-ES/MS and all of the W values by aqua regia ICP-ES/MS are below the lower detection limits. Seventy-two per cent of the four-acid ICP-ES/MS results for S are below the lower detection limits, as are 31% of the Sn values by ICP-ES/MS. Determinations that are above, but close to, the lower detection limits are likely to exhibit poor accuracy and precision.

Table 2. Elements for which fusion ICP-ES and LECO (total C and S) analyses (Acme method code 4A) returned values below lower detection limits.

Parameter	Ni (ppm)	S (total; %)
LDL ¹	20	0.01
Number of samples	68	68
Values < LDL	3	3
Percentage < LDL	4.4	4.4

¹ lower detection limit

6.2 Certified Reference Material

6.2.1 Percentage Recovery

To estimate the analytical accuracy of the analyses, three samples of CANMET certified reference material (standard) Till-2 were introduced into the sample batch at the AGS laboratory in Edmonton prior to shipping. Results for the Till-2 standard obtained by Acme are compared to the recommended values provided by CANMET using percentage recovery values (Tables 6–9). Percentage recovery, which represents a measure of accuracy, is defined by the following equation (cf. Ziegler and Combs, 1997):

$$\text{Percentage recovery} = 100 \times C_M/C_A,$$

where

C_M = the measured concentration of the standard sample

C_A = the actual concentration of the standard sample (recommended or provisional value)

Percentage recovery values near 100% indicate a high degree of accuracy.

If 50% or less of the results for an element were below the lower detection limit (LDL), the <LDL values were set to $0.5 \times \text{LDL}$ for the percentage recovery calculation. If more than 50% of the results for an element were below the LDL, the percentage recovery was not calculated. In addition, the Till-2 standard is not adequately characterized for some elements, thereby precluding percentage recovery calculations.

Percentage recovery values for determinations by ICP-ES (following fusion) are generally within 5% of 100%. Percentage recovery values for determinations by fusion ICP-ES/MS and four-acid ICP-ES/MS are generally within 15% of 100%. Low percentage recovery values (<85%) by four-acid ICP-ES/MS for Zr, Hf, Be, Y, Ta, Nb, U, W and Ti largely reflect limited digestion of oxide minerals by the four-acid method.

Many of the percentage recovery values are below 75% for the determinations by aqua-regia ICP-ES/MS. Aqua regia provides only partial digestion of silicates and oxides.

Table 6. Summary of fusion ICP-ES and gravimetric (loss-on-ignition) percentage recovery results for three CANMET Till-2 samples (Acme method code 4A).

>125% and ≤150%	Bi
>150%	

6.2.2 Relative Standard Deviation

For data sets with replicate determinations of a particular standard sample (e.g., Till-2), the relative standard deviation (RSD) provides a measure of precision. The RSD is defined by the following equation:

$$\text{RSD} = s/x,$$

where

RSD = relative standard deviation

s = standard deviation

x = mean of replicate determinations

Low RSD values indicate a high degree of precision.

If 50% or less of the results for an element were below the lower detection limit (LDL), the <LDL values were set to 0.5 x LDL for the RSD calculation. If more than 50% of the results for an element were below the LDL, the RSD was not calculated.

Most of the RSD values for determinations by ICP-ES (following fusion) are below 2%. The RSD values for determinations by fusion ICP-MS, four-acid ICP-ES/MS and aqua-regia ICP-ES/MS are generally less than 5%, although values of up to 10% are not uncommon (Tables 10–13).

Table 10. Summary of 1) fusion ICP-ES, 2) LECO (total C and S), and 3) gravimetric (loss-on-ignition) relative standard deviation (RSD) results for three CANMET Till-2 samples (Acme method code 4A).

6.3 Laboratory Duplicate Pairs

6.3.1 Relative Percentage Difference

The batch of samples submitted to Acme included four ‘blind’ laboratory duplicate pairs created by splitting <63 µm sample material at the AGS laboratory. Analytical results for these duplicate pairs are summarized in Tables 14–17, in which the relative percentage difference (RPD) represents a measure of precision (cf. Ziegler and Combs, 1997; Zimmerman et al., 2001). The RPD for a set of duplicate-pair results is defined by the following equation:

$$RPD = 100 \times |C_1 - C_2| / C_X$$

where

RPD = relative percentage difference

$|C_1 - C_2|$ = absolute value of the difference between the two concentrations

C_X = mean of the two results

If values below the lower detection limit (LDL) were returned for an element in both samples of a duplicate pair, that pair was removed from the RPD calculation for that element. If a given duplicate pair returned one value below the LDL and one measurable value, then the <LDL value was set to 0.5 x LDL for the purpose of the RPD calculation.

Analytical differences between the laboratory duplicate pairs should reflect 1) the homogeneity of the sieved samples and 2) the analytical precision (low values indicating a high level of homogeneity and analytical precision). The RPD values for major-oxide determinations at Acme by ICP-ES (following fusion) are generally less than 5%. For the other methods, most RPD values are less than 10%.

Table 14. Summary of 1) fusion followed by ICP-ES, 2) LECO (total C and S), and 3) gravimetric (loss-on-ignition) relative percentage difference (RPD) results for four laboratory duplicate pairs (Acme method code 4A).

7 Discussion

7.1 Till Stratigraphy

Based on the results of an auger-coring program, Fenton et al. (2006b) identified two distinct till units in the Sawn Lake area based on stratigraphic relationships and geochemical results: an upper (surface) till and a lower till. At some of the coring sites, the two till units are separated from one another by intervening glaciofluvial and glaciolacustrine sediments. The lower till, in some cores, exhibited a weathering profile similar to that seen in the modern surficial sediments, indicating a prolonged nonglacial period. Geochemical criteria listed by Fenton et al. (2006b) to distinguish the upper till from the lower till include lower Ti values (generally <0.7% TiO₂ in the upper till), higher Ca values (generally >2.4% CaO in the upper till) and greater dolomite contents (generally >3.0% in the upper till).

The relationships between TiO₂, CaO and dolomite contents obtained from the 2002 Sawn Lake area till samples are shown in Figures 6 and 7. The majority of samples have characteristics typical of the upper till unit. Samples with low (<0.7%) TiO₂ values (typical of the upper till) and low CaO (<2.4%) and dolomite (<3.0%) contents (typical of the lower till) probably represent upper till material from which some of the carbonate has been leached.

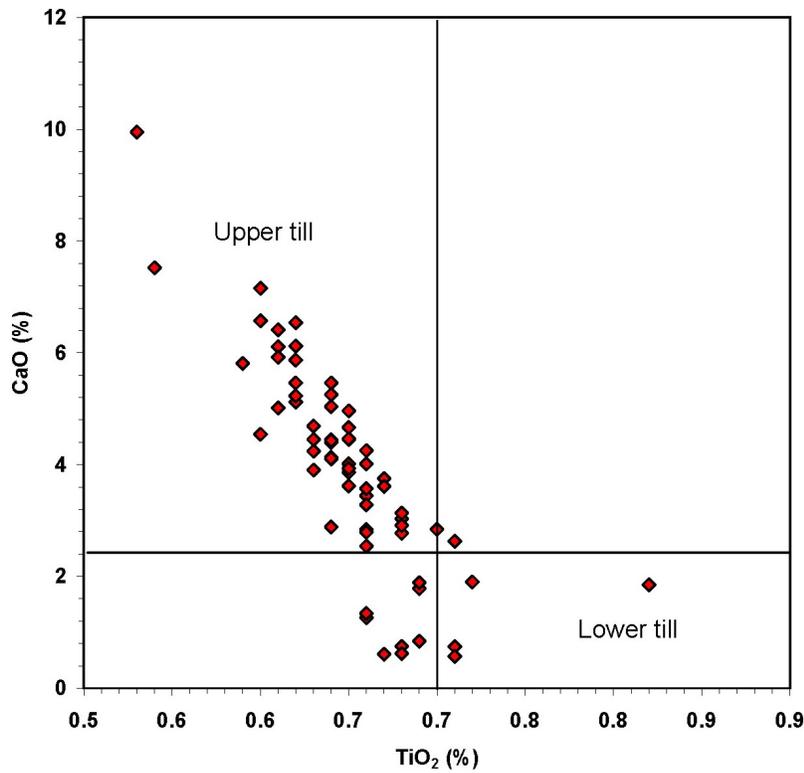

Figure 6. Binary diagram showing TiO_2 and CaO contents in till from the Sawn Lake area. Discrimination boundaries from Fenton et al. (2006b).

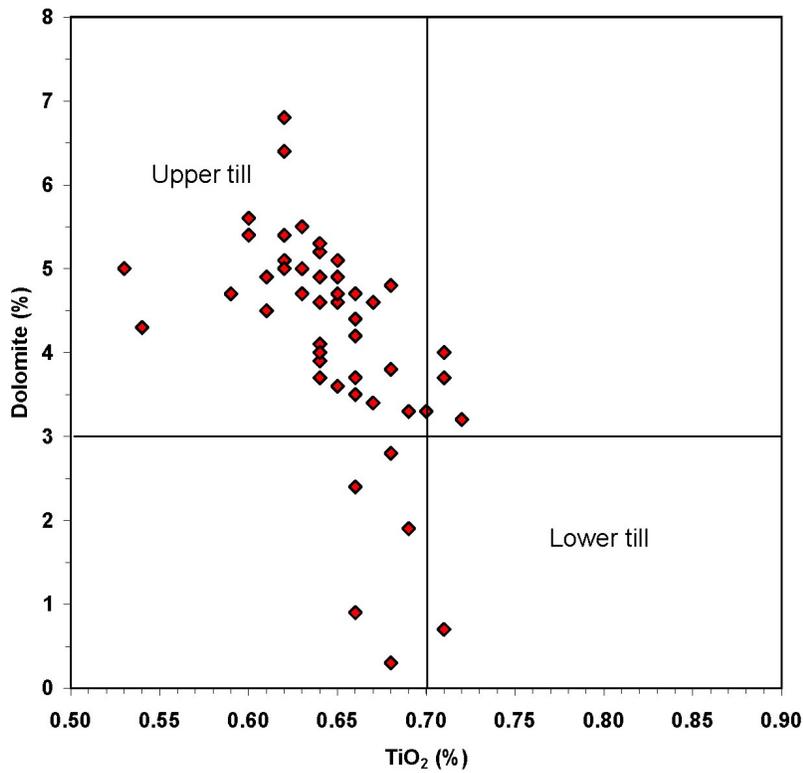

Figure 7. Binary diagram showing TiO_2 and dolomite contents in till from the Sawn Lake area. Discrimination boundaries from Fenton et al. (2006b).

7.2 Till Geochemistry and Kimberlites

7.2.1 Background

Previous studies have demonstrated that geochemical surveying of till and soil may be successfully applied to diamond (kimberlite) exploration (McClenaghan and Kjarsgaard, 2001; Seneshen et al., 2005). However, B- and C-horizon samples collected on traverses across and near the K4B kimberlite in the Sawn Lake area, reported by Fenton et al. (2006a), did not reveal the presence of the kimberlite (although elevated Mg/Fe, Ni/V and B values were detected in organic soils collected during the same sampling program).

If kimberlite-related geochemical anomalies exist in till near some of the kimberlites in the Sawn Lake area, the sample spacing is a principal factor governing the probability of detecting one or more the anomalies. During focused sampling programs, the spacing between samples can be 100 m or less. In contrast, the distances between the till samples discussed in this report are commonly 1–4 km.

7.2.2 Element Selection

Kimberlite pathfinder elements in till may include Mg, Ni, Cr, Co, V, Mn, Fe, La, Ce, Nd, Sm, Nb, Ti, P, Ba, Ta, Hf, Zr and Sr (e.g., McClenaghan and Kjarsgaard, 2001). The effectiveness of a particular element as a pathfinder will depend, in part, on the contrast between 1) that element in kimberlite and 2) that element in the hostrocks and up-ice country rocks from which the majority of the till is derived. The kimberlites' hostrocks and the country rocks in the Buffalo Head Hills consist largely of Cretaceous marine shale. Comparisons of average kimberlite composition (Mitchell, 1986) and average Buffalo Head Hills kimberlite composition (Eccles and Luth, 2003) to average shale composition (Krauskopf, 1979) indicate that Mg, Cr, Ni and Nb may provide the greatest anomaly contrasts in this geological setting.

7.2.3 Till Geochemistry and Kimberlite-Indicator Mineral Counts

The abundance of KIM grains in till at a given site may serve as a proxy for the proportion of kimberlite incorporated within the till during glaciation. However, the igneous abundance and type of kimberlite-indicator minerals vary widely between kimberlites in the Buffalo Head Hills (Hood and McCandless, 2003, 2004), and olivine in some of the kimberlites has undergone alteration to serpentine and carbonate (Eccles et al., 2004).

The Mg, Cr, Ni and Nb contents in the <63 µm fraction of the till are plotted against KIM counts (picked pyrope, Cr-diopside, eclogitic garnet, olivine, picroilmenite and chromite grains; Prior et al., 2005) normalized to a 30 kg sample in Figures 8 to 11. No correlations are evident in these diagrams.

7.2.4 Areal Distribution of Mg, Cr, Ni and Nb

The MgO, Cr, Ni and Nb values in near-surface tills of the Sawn Lake area are shown in Figures 12–15. No significant relationships between these elements and the known kimberlites are evident (note that the till sample spacing used in this survey was not designed to investigate relationships between kimberlites and till geochemistry).

7.3 Till Geochemistry and Till Types

Alberta Energy and Utilities Board/Alberta Geological Survey Map 314 (Trommelen et al., 2006), which shows the surficial geology of the Sawn Lake map area at a scale of 1:50 000, has been used to characterize individual till samples as being collected from ablation till or non-ablation till. On Map 314, ablation till dominates within areas mapped as stagnant-ice moraine (map unit MS), whereas non-ablation till (which includes basal till) dominates within areas mapped as moraine (map unit M; Trommelen, 2004; Trommelen et al., 2006; R. Paulen, pers. comm., 2010). Twenty-four samples are classified as ablation till and 35 samples are classified as non-ablation till. Eight samples were not classified because they were collected either 1) from till beneath glaciofluvial sediments or 2) near unit contacts.

Histograms of Mo and U in ablation till and non-ablation till are presented in Figure 16; these elements are plotted against each other in Figure 17. The figures show that samples of ablation till generally returned lower Mo and U values than samples of non-ablation till. A map of Mo values in till of the Sawn Lake area shows generally lower values in the northwestern part of the map area, where ice-stagnation deposits dominate the surficial geology (Figure 18). Median values for selected oxides and elements in ablation till and non-ablation till of the Sawn Lake area are listed in Table 18. Note that the ablation till has higher MgO, CaO, calcite and dolomite median values, whereas the non-ablation till (which includes basal till) has higher Mo, U, Sb and Se median values.

A plausible explanation for this relationship is that the non-ablation till contains a significant amount of basal till derived mainly from Cretaceous shale containing elevated Mo, U, Sb, Hg and Se values, particularly organic-rich shale such as the Second White Specks Formation (Dufresne et al., 2001; Fraser, 2005). In contrast, the ablation till may contain a somewhat greater amount of far-travelled material, including Paleozoic limestone and dolomite.

7.4 Till Texture

Results of texture analyses of samples collected in 2002 indicate that tills in the Sawn Lake area typically contain about 40% clay, 30% silt and 30% sand (Table 19 and Appendix 1). The median values indicate that ablation till tends to have slightly higher sand content and slightly lower silt and clay contents than the non-ablation till, but there is considerable overlap in the data.

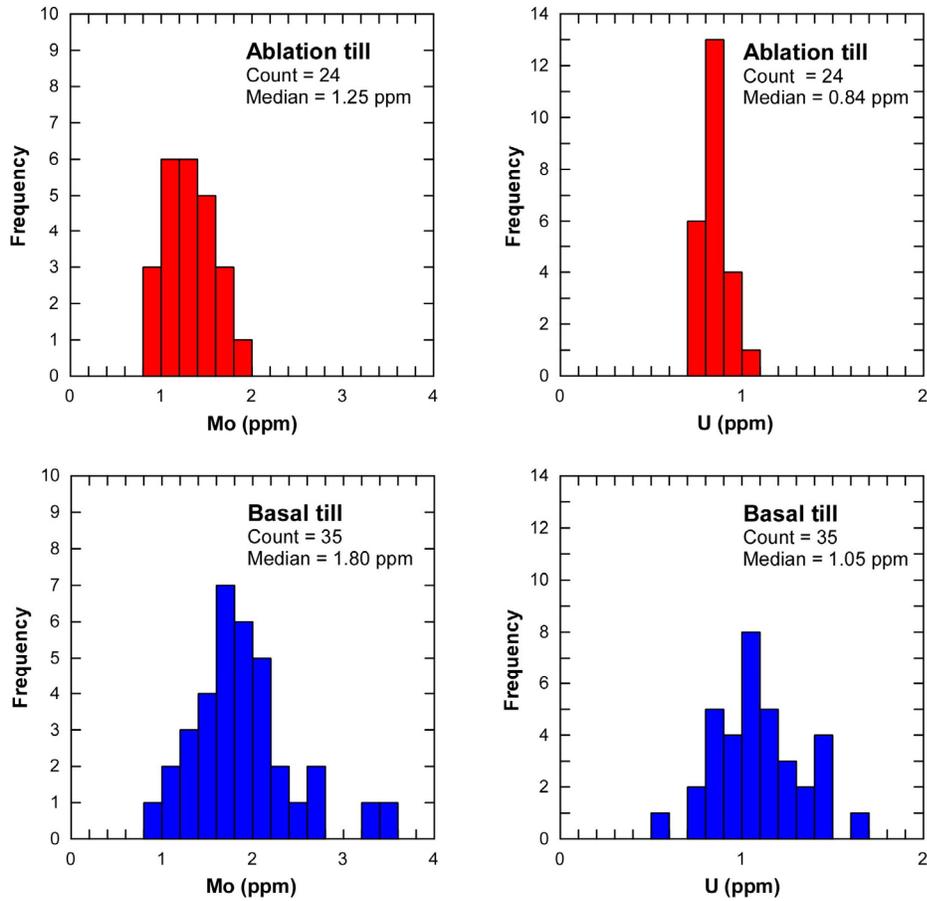

Figure 16. Histograms of Mo and U in samples of ablation till and non-ablation till from the Sawn Lake area.

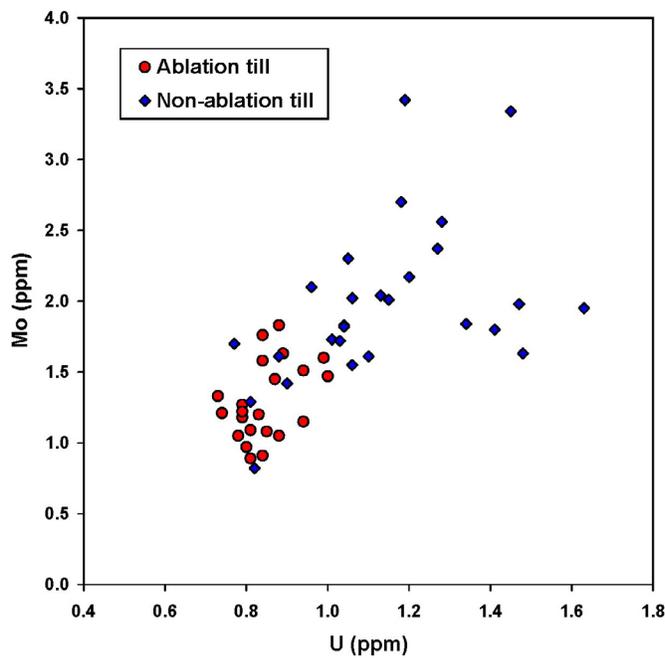

Figure 17. Plot of U versus Mo in samples of ablation till and non-ablation till from the Sawn Lake area.

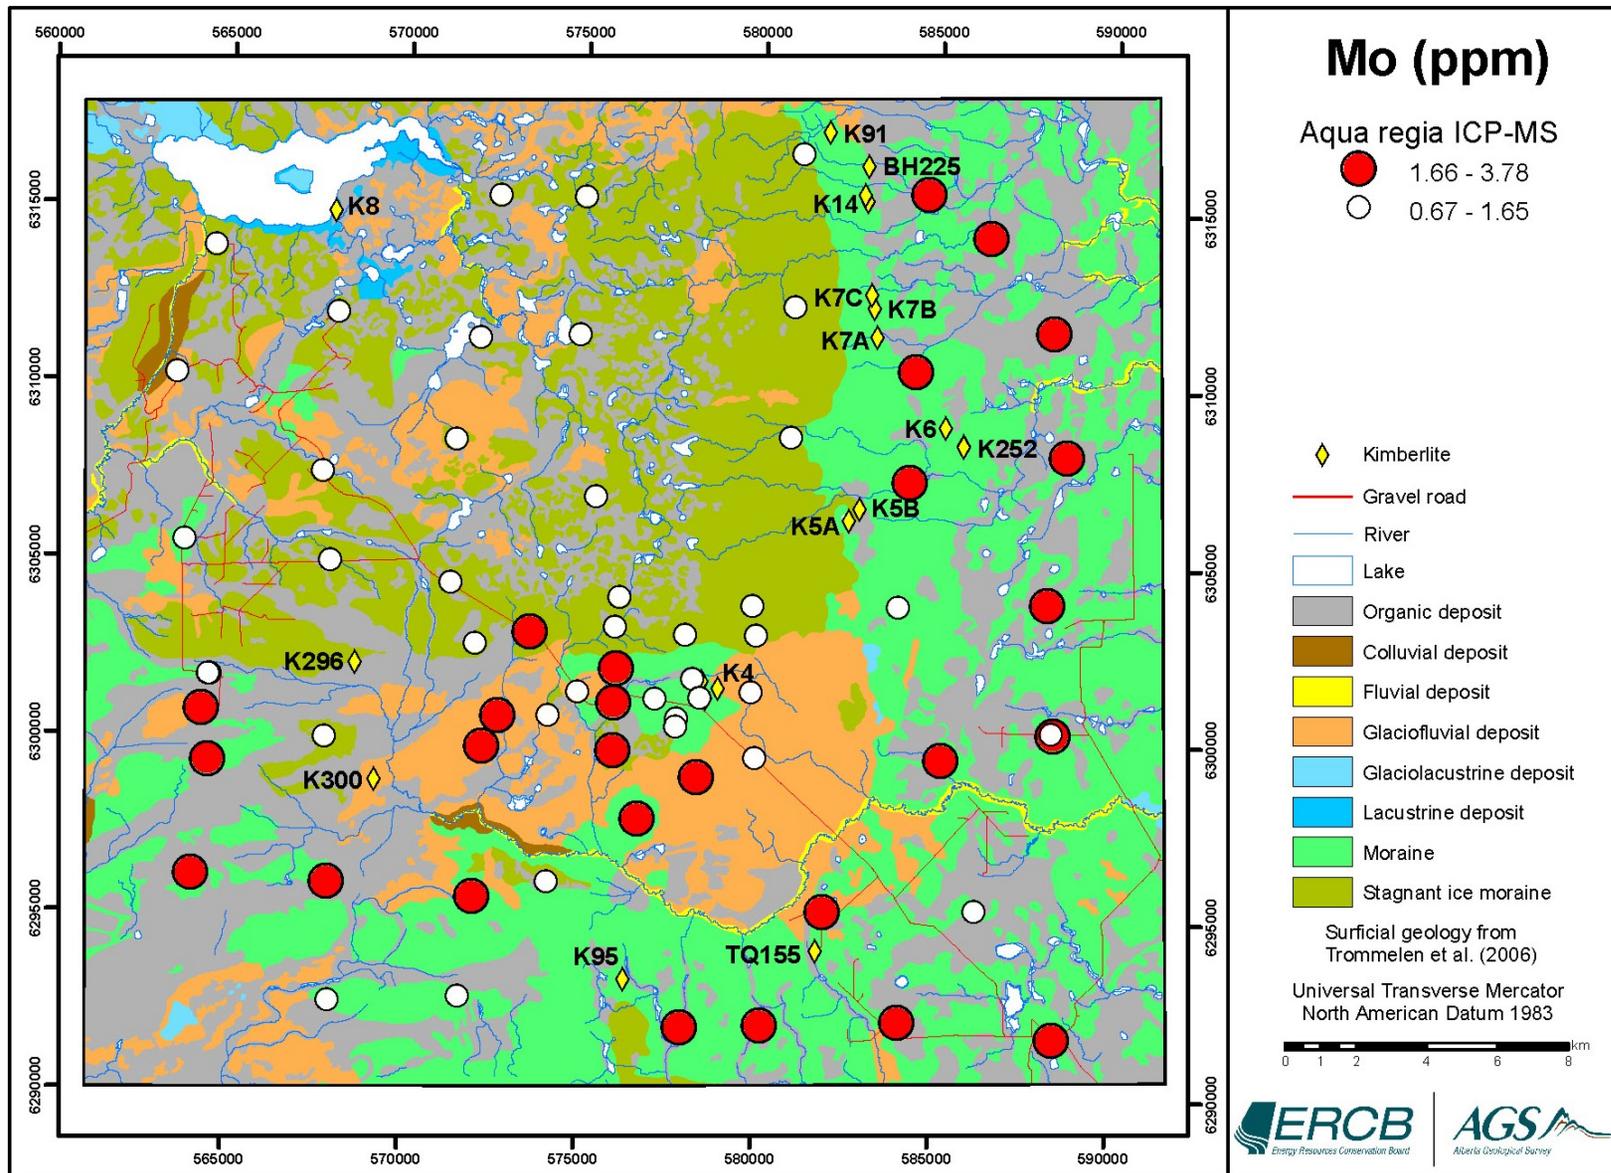

Figure 18. Distribution of Mo in till of the Sawn Lake map area.

Table 18. Comparison of geochemical data obtained from ablation till and non-ablation till.

Component	Method	Ablation till median (n = 24)	Non-ablation till median (n = 35)
MgO	Fusion-ICP	1.91%	1.77%
CaO	Fusion-ICP	4.42%	3.75%
Mo	Aqua regia-ICP-MS	1.25 ppm	1.80 ppm
U	Aqua regia-ICP-MS	0.84 ppm	1.05 ppm
Sb	Aqua regia-ICP-MS	0.39 ppm	0.47 ppm
Se	Aqua regia-ICP-MS	0.2 ppm	0.4 ppm
Calcite	Chittick	3.6%	2.8%
Dolomite	Chittick	4.9%	3.7%

Table 19. Comparison of textural data obtained from ablation and basal till.

Component	Size Range	Ablation till median (n = 22)	Non-ablation till median (n = 27)
Sand	0.063 to 1 mm	31.1%	27.1%
Silt	4 to 63 µm	29.7%	32.1%
Clay	<4 µm	39.3%	40.3%

Appendix 1 – Analytical Data

Explanatory Notes

Unit: Refers to map unit (sediment type) on Alberta Energy and Utilities Board/Alberta Geological Survey Map 314 (Trommelen et al., 2006), as follows:

M: moraine (includes basal till)

MS: stagnant-ice moraine (ablation till)

FG: glaciofluvial

unknown: sample from either 1) an area mapped as glaciofluvial (including samples of till collected beneath glaciofluvial material), or 2) a location near the mapped boundary between different moraine units on Map 314

1EX: four-Acid ICP-ES/MS analysis (Acme Group 1EX)

1F: aqua-regia ICP-ES/MS analysis (Acme Group 1F)

4A: fusion ICP-ES analysis of oxides, Ba, Ni and Sc, LECO analysis of C and S and gravimetric analysis of loss-on-ignition (Acme Group 4A)

4B: fusion ICP-MS analysis (Acme Group 4B)

Sum: total of the oxides, Ba, Ni, Sc and loss-on-ignition determined by the Acme 4A analytical methods

na: not analyzed or not applicable

1–2 mm sand (%): proportion of 1–2 mm sand in entire sample

.063–1 mm sand (%): proportion of 0.063–1 mm sand in the <1 mm fraction

4–63 µm silt (%): proportion of 4–63 µm silt sand in the <1 mm fraction

<4 µm clay (%): proportion of <4 µm clay the <1 mm fraction

.05–1 mm sand (%): proportion of 0.05–1 mm sand in the <1 mm fraction

2–50 µm silt (%): proportion of 2–50 µm silt sand in the <1 mm fraction

<2 µm clay (%): proportion of <2 µm clay the <1 mm fraction
